Error Detection and Correction

Data can be corrupted during transmission.

Some applications require that errors be detected and corrected.

Let us first discuss some issues related, directly or indirectly, to error detection and correction.

Topics discussed in this section:

Types of Errors Redundancy Detection Versus Correction Forward Error Correction Versus Retransmission Coding Modular Arithmetic

In a single-bit error, only 1 bit in the data unit has changed.

Single-bit error

A burst error means that 2 or more bits in the data unit have changed.

Burst error of length 8

To detect or correct errors, we need to send extra (redundant) bits with data.

The structure of encoder and decoder

In this lecture, we concentrate on block codes; we leave convolution codes to advanced texts.

In modulo-N arithmetic, we use only the integers in the range 0 to N −1, inclusive.

XORing of two single bits or two words

 $0 \oplus 0 = 0$

1 + 1 = 0

1 + 0 = 1

a. Two bits are the same, the result is 0.

 $0 \oplus 1 = 1$

b. Two bits are different, the result is 1.

	1	0	1	1	0	
+	1	1	1	0	0	
	0	1	0	1	0	_

c. Result of XORing two patterns

In block coding, we divide our message into blocks, each of k bits, called datawords. We add r redundant bits to each block to make the length n = k + r. The resulting n-bit blocks are called codewords.

Topics discussed in this section:

Error Detection Error Correction Hamming Distance Minimum Hamming Distance

Datawords and codewords in block coding

2^k Datawords, each of k bits

2ⁿ Codewords, each of n bits (only 2^k of them are valid)

The 4B/5B block coding discussed in Chapter 4 is a good example of this type of coding. In this coding scheme,

k = 4 and n = 5. As we saw, we have $2^k = 16$ datawords and $2^n = 32$ codewords. We saw that 16 out of 32 codewords are used for message transfer and the rest are either used for other purposes or unused.

Error Detection

- Enough redundancy is added to detect an error.
- The receiver knows an error occurred but does not know which bit(s) is(are) in error.
- Has less overhead than error correction.

Process of error detection in block coding

Example 2

Let us assume that k = 2 and n = 3. Table 10.1 shows the list of datawords and codewords. Later, we will see how to derive a codeword from a dataword.

Assume the sender encodes the dataword 01 as 011 and sends it to the receiver. Consider the following cases:

1. The receiver receives 011. It is a valid codeword. The receiver extracts the dataword 01 from it.

Example 2 (continued)

- 2. The codeword is corrupted during transmission, and 111 is received. This is not a valid codeword and is discarded.
- **3.** The codeword is corrupted during transmission, and 000 is received. This is a valid codeword. The receiver

incorrectly extracts the dataword 00. Two corrupted bits have made the error undetectable.

Table 1 A code for error detection (Example 10.2)

Datawords	Codewords		
00	000		
01	011		
10	101		
11	110		

An error-detecting code can detect only the types of errors for which it is designed; other types of errors may remain undetected.

Structure of encoder and decoder in error correction

Let us add more redundant bits to Example 10.2 to see if the receiver can correct an error without knowing what was actually sent. We add 3 redundant bits to the 2-bit dataword to make 5-bit codewords. Table 10.2 shows the datawords and codewords. Assume the dataword is 01. The sender creates the codeword 01011. The codeword is corrupted during transmission, and 01001 is received. First, the receiver finds that the received codeword is not in the table. This means an error has occurred. The receiver, assuming that there is only 1 bit corrupted, uses the following strategy to guess the correct dataword.

Example 3 (continued)

- **1.** Comparing the received codeword with the first codeword in the table (01001 versus 00000), the receiver decides that the first codeword is not the one that was sent because there are two different bits.
- 2. By the same reasoning, the original codeword cannot be the third or fourth one in the table.
- 3. The original codeword must be the second one in the table because this is the only one that differs from the received codeword by 1 bit. The receiver replaces 01001 with 01011 and consults the table to find the dataword 01.

Dataword	Codeword		
00	00000		
01	01011		
10	10101		
11	11110
